Introduction

Methane (CH₄) is a potent greenhouse gas, with a global warming potential approximately 28 times that of CO₂. The EU's CANMILK project aims to mitigate the emissions of barn CH₄ using plasma catalysis at low temperatures. For this, plasma-activated NO_X should help oxidize small quantities of CH₄ (\leq 1%) mixed in barn air. However, optimizing these systems is challenging due to the complexity of plasma-surface interactions and a lack of predictive kinetic models.

We develop a kinetic model from a data-rich proxy system: the plasma-catalytic removal of CH_4 - NO_x from LNG engine exhaust, as studied by [1]. It consists of a self-consistent Differential-Algebraic Equation (DAE) model, based on a kinetic scheme assuming a single rate-limiting step per global reaction, with all other elementary reactions in a fast equilibrium regime.

This work establishes a first attempt to create a modelling tool that provides the foundation for designing reactors for the CANMILK project's methane abatement applications.

The Plasma-Catalytic System for Model Validation

The model is validated against the experimental work by [1], that investigates the removal of CH_4 and NO_x using a Dielectric Barrier Discharge (DBD) plasma reactor followed by a catalytic reactor. The catalyst consists of a physical mixture of 2% Cr-2% In/SSZ-13 (Si/Al=10) and Co/SSZ-12 (Si/Al = 10). The model addresses the catalytic kinetics.

Overall Reaction: The system is governed by four key global reactions.

CR1
$$2 \operatorname{NO} + \operatorname{O}_2 \Longrightarrow 2 \operatorname{NO}_2$$

CR2 $\operatorname{CH}_4 + 2 \operatorname{NO}_2 \longrightarrow \operatorname{CO}_2 + \operatorname{N}_2 + 2 \operatorname{H}_2 \operatorname{O}$

CR3 $\operatorname{CH}_4 + 2 \operatorname{O}_2 \longrightarrow \operatorname{CO}_2 + 2 \operatorname{H}_2 \operatorname{O}$

CR4 $2 \operatorname{CO} + \operatorname{O}_2 \longrightarrow 2 \operatorname{CO}_2$

Our goal is to create a predictive model that captures the system's dynamics based on elementary reaction steps in a self-consistent way.

Model Formulation: A DAE Approach

The model is based on a detailed kinetic scheme [1], formulated as a system of Differential-Algebraic Equations (DAEs) that couple the gas-phase kinetics with the surface chemistry.

Key Assumptions:

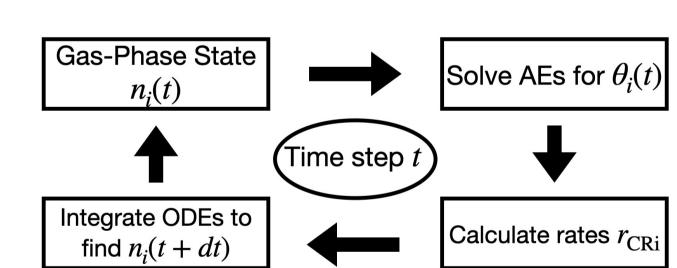

- Rate-Limiting Step (→): For each of the four global reactions (CR1-CR4), one elementary step is assumed to be slow and rate-determining.
- Fast Equilibrium (\iff): All other elementary steps are assumed to be in fast equilbrium regime.

$$\begin{array}{c} \text{CR1} \\ \text{O}_2(\text{g}) + \text{s} \Longrightarrow \text{O}_{2s} \\ \text{NO}(\text{g}) + \text{O}_{2s} \longleftrightarrow \text{NO}_2(\text{g}) + \text{O}_s \\ \text{NO}(\text{g}) + \text{O}_{2s} \longleftrightarrow \text{NO}_2(\text{g}) + \text{O}_s \\ \text{NO}(\text{g}) + \text{O}_s \rightleftharpoons \text{NO}_{2s} \\ \text{NO}_2(\text{g}) + \text{S} \rightleftharpoons \text{NO}_s \\ \text{CR4} \\ \text{CO}(\text{g}) + \text{s} \rightleftharpoons \text{CO}_s \\ \text{O}_2(\text{g}) + 2 \text{ b} \rightleftharpoons 2 \text{ O}_b \\ \text{CO}_s + \text{O}_b + \text{CH}_4(\text{g}) \Longrightarrow \text{CO}_{2s} + \text{b} \\ \text{CO}_2(\text{g}) + \text{S} \rightleftharpoons \text{CO}_2(\text{g}) + \text{S} \\ \text{CO}_{2s} \rightleftharpoons \text{CO}_2(\text{g}) + \text{S} \\ \text{CO}_{2s} \rightleftharpoons \text{CO}_2(\text{g}) + \text{S} \\ \end{array} \begin{array}{c} \text{CR2} \\ \text{CR3} \\ \text{CR3} \\ \text{CR3} \\ \text{CH}_4(\text{g}) + \text{s} \rightleftharpoons \text{CH}_{4s} \\ \text{CH}_4(\text{g}) + \text{s} \rightleftharpoons \text{CH}_{4s} \\ \text{CH}_{4s} + \text{O}_s \Longrightarrow \text{CH}_{3s} + \text{OH}_s \\ \text{CH}_{3s} + \text{O}_s \rightleftharpoons \text{CH}_{3s} + \text{OH}_s \\ \text{CH}_{3s} + \text{O}_s \rightleftharpoons \text{CHO}_s + \text{H}_s \\ \text{CH}_{5s} + \text{O}_s \rightleftharpoons \text{CHO}_s + \text{H}_s \\ \text{CH}_{5s} + \text{O}_s \rightleftharpoons \text{CHO}_s + \text{H}_s \\ \text{CH}_{5s} + \text{O}_s \rightleftharpoons \text{CH}_{5s} + \text{OH}_s \\ \text{CH}_{5s} + \text{O}_s \rightleftharpoons \text{CO}_s + \text{OH}_s \\ \text{CH}_{5s} + \text{OH}_s \rightarrow \text{CO}_s \rightarrow \text{OH}_s \\ \text{CH}_{5s} + \text{OH}_s \rightarrow \text{CH}_{5s} \rightarrow \text{CO}_s \rightarrow \text{OH}_s \\ \text{CH}_{5s} + \text{OH}_s \rightarrow \text{CH}_{5s} \rightarrow \text{CH$$

s and n represent two different catalyst active sites and b indicates catalyst oxygen vacancies [1].

The DAE Structure: Coupling Gas and Surface

The set of assumptions creates a coupled system. The gas-phase concentrations evolve according to ODEs, but at any instant, the surface coverages are governed by a set of AEs.

The Algebraic Equations (AEs): Surface Chemistry at Equilbrium

The fast equilibrium assumption allows to express surface coverages (θ_i) as function of partial pressures (p_i) and the free surface variables (θ_{free}) :

$$\theta_i = f_i(p_j(t), \theta_{\text{free}})$$

Example: For adsorbed oxygen, the coverage is given by: $\theta_{O_{2,S}} = K_1 p_{O_2} \theta_S$

The Differential Part (ODEs): Gas-Phase Dynamics

The evolution of species densities is described by ODEs whose rates depend on the surface coverages calculated from the AEs [2,3].

Example: The change for CH_4 depends on the rates CR2 and CR3, which are themselves functions of the surface state θ :

$$\frac{d}{dt}[CH_4] = -r_{CR2}(\theta, p) - r_{CR3}(\theta, p)$$

with $r_{CR2}=k_{CR2-3}p_{NO_2}p_{CH_4}\theta_n$ and $r_{CR3}=k_{CR3-2}\theta_{CH_4s}\theta_{Os}$. Here, the k_{CRi-j} correspond to the reaction rate of the slow elementary step.

This structure creates the essential coupling between *fast* surface chemistry and the *slower* gasphase evolution.

Constrained Optimization

Since the system of AEs for the s catalyst sites is under-determined, as we have more free variables $(\theta_{free} = [\theta_s, \theta_{OHs}, \theta_{CHs}])$ than constraints (site conservation), we have a non-unique solution. As a result, we consider a constrained optimization problem to find a unique and physically meaningful solution at each time step. We minimize the following objective function subjected to the AE constraints:

$$\min_{\theta_{free}} [\lambda |\theta_{free}|_2^2 + (1-\lambda)|\Delta\theta_{free}/\Delta t|_2^2]$$

The first term corresponds to the *Tikhonov* regularization and selects the solution with the smallest L_2 -norm. The second one ensures a smooth evolution by penalizing unphysical jumps between consecutive time steps. While we set $\lambda=0.9$, the model is robust to variations in this hyperparameter.

Parameter Determination

The parameters used for the model combine physical constraints from literature with data-driven optimization. The rate constants in our model follow the Arrhenius equation, $K_i = Ae^{-E_i/RT}$, which depends on:

- 1. Energy Barriers or Adsorption Enthalpies (E_i)
- 2. Steric Factors (A_i)

The Energy Barriers for the fast and slow chemical reactions from the reaction scheme were adopted directly from [1].

The Steric Factors of the fast and slow reactions were determined through a data-driven optimization. Those parameters were fitted by minimizing the error between our model's predictions and the experimental dataset from [1].

Results

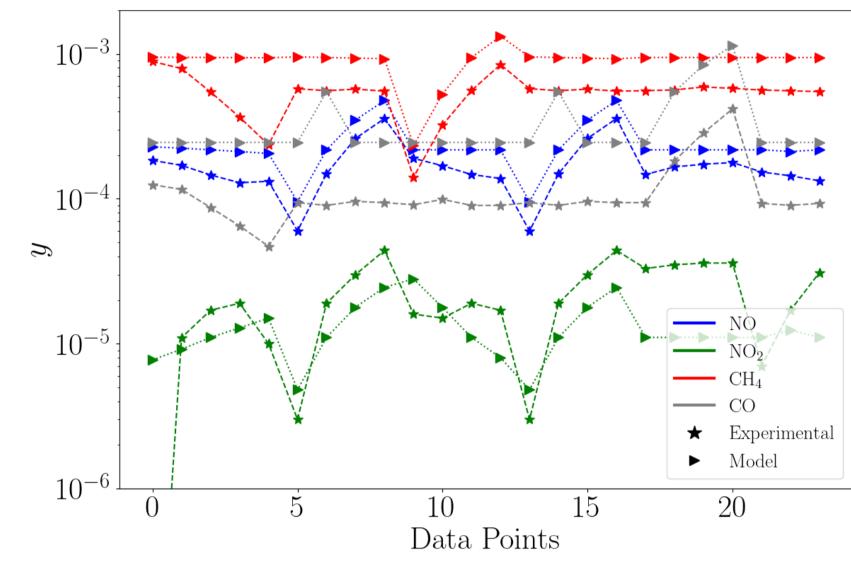

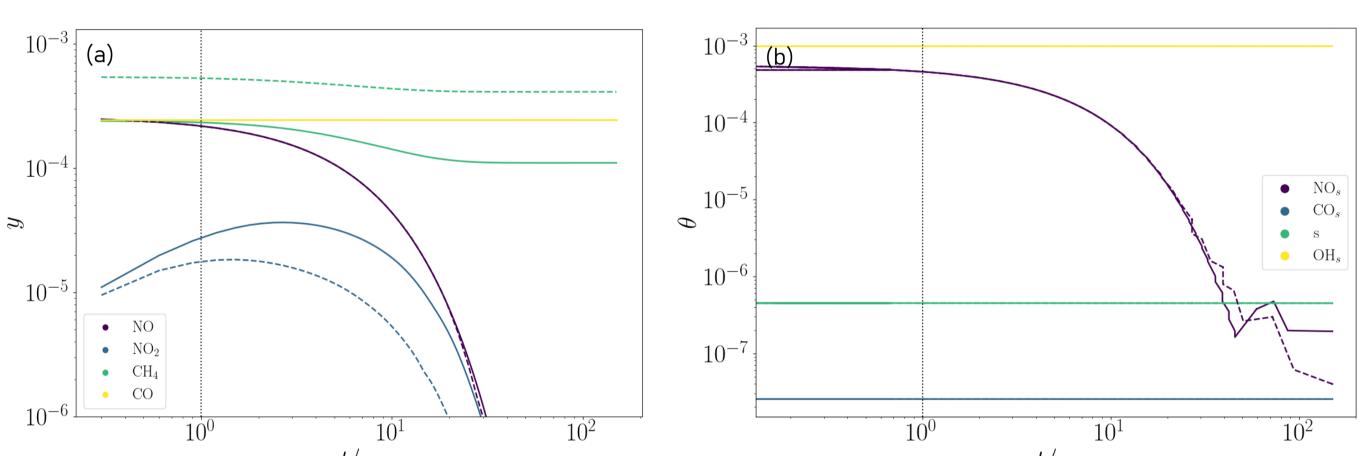

Figure 1: Comparison of DAE model predictions against experimental data [1] of fractions of key species (NO, NO₂, CH₄ and CO). Experimental conditions: $429-520^{\circ}$ C, with fixed H₂O (13%), O₂ (6.8%) and CO₂ (7.8%). Inlet concentrations of CO, NO, and CH₄ vary for each point, but their sum is around 1500 ppm.

As shown in Figure 1, our DAE model reproduces the experimental trends observed by [1], The model captures the behavior of NO_X species across a range of operating temperatures and inlet concentrations. However, the model consistently overpredicts CH_4 and CO fractions.

Figures 2: Simulated temporal evolution of key chemical species fractions under experimental conditions. The conditions were set to 478°C with a gas mixture of H_2O (13%), O_2 (6.8%), CO_2 (7.8%), CO_3 (7.8%), CO_3 (245 ppm) and CO_3 (260 ppm). (a) Normalized density CO_3 of key gas-phase species. (b) Surface coverage CO_3 on the catalyst's sites CO_3 . Simulations were performed with two different CO_4 concentations: 240 ppm (solid lines) and 540 ppm (dashed lines).

As shown in Figure 2, CH_4 and NO are consumed over time. Moreover, NO_2 is formed and subsequently destroyed.

The results from Figure 1 were obtained with residence time $t=\tau_c\approx 0.04$ secs, replicating the experimental conditions.

Conclusions:

- The model captures the qualitative trends and temporal evolution of the key reactive gaseous species (NO, NO₂, CH₄ and CO), but it consistently underpredicts the final concentrations of CO and CH₄ when compared to experimental data.
- The disagreement suggests that the model's core assumptions for surface evolution are too restrictive. Relaxing these assumptions is the primary path towards improving quantitative accuracy.
- The model predicts that the residence time required for significant CH_4 removal is ~ 20 times the catalytic residence time (τ_c) from [1], providing a clear hypothesis for future experimental validation.

Perspectives:

- Extend the model to simulate industrially relevant conditions, such as bairn air treatment, which involves higher CH_4 concentrations (up to 1%) and the effects of plasma activation (NO_x up to 5%).
- Enhance the model's predictive power by replacing empirical parameters with high-fidelity energy barriers computed from first-principle simulations (DFT and Molecular Dynamics).
